## ABSTRACT

Ischemic heart disease IHD is a rapidly increasing common cause of death in the world. This disease is the insufficient status of oxygen within the cardiac muscles due to an imbalance between oxygen supply and demand, and a cardiac disease that occurs as a result of coronary artery stenosis. Ischemic heart disease diseases are the leading cause of death in both developed and developing countries ,among these IHD is the most prevalent manifestation and is associated with high mortality and morbidity. The clinical presentation of IHD include silent ischaemia, stable angina, unstable angina, myocardial infarction, heart failure and sudden death.

**Keywords:** *Ischemic, IHD, sudden death.*

## INTRODUCTION

The rate of cardiovascular infections among diabetic patients is so tall that diabetes mellitus is as of now characterized as a cardiovascular malady comparable. Moreover, diabetic patients who create intense coronary disorders have a poorer short-term and long-term guess, so essential and auxiliary preventive measures are basically imperative in this populace subgroup. There's considerable prove that pharmacological treatment for essential and auxiliary cardiovascular avoidance is more compelling in diabetic patients than in non-diabetics. This article audits the prove of the adequacy of pharmacological avoidance treatments in diabetic patients in favor of a forceful pharmacological preventive technique.

Each diabetic understanding without known cardiovascular illness ought to be treated with angiotensin-converting chemical inhibitors and statins. High-risk patients ought to too get low-dose ibuprofen. Compared with non-diabetics, diabetic patients who create intense coronary occasions advantage more from the expansion of seriously antithrombotic treatment to ibuprofen treatment. Diabetic patients showing with non-ST portion rise disorders have superior results when treated with clopidogrel or glycoprotein IIb/IIIa inhibitors, and diabetics displaying with ST-segment height or cleared out bundle-branch piece have a more noteworthy survival advantage when given thrombolytic treatment compared with non-diabetic

patients. Unless formal contraindications are display, diabetic patients with ischemic heart infection, especially those with past myocardial localized necrosis, ought to continuously be treated with headache medicine, betablockers, angiotensin changing over protein inhibitors, and statins, notwithstanding of lipid levels, cleared out ventricular.

The most cause of passing in diabetics is cardiovascular illness, especially ischemic heart illness (IHD). In truth, the chance of enduring cardiovascular complications of patients with DM is so tall that its forecast is comparable to that of people without diabetes who have endured past intense myocardial dead tissue (AMI).<sup>1</sup> For that reason, in numerous regions diabetes is considered comparable to build up cardiovascular infection.

For this reason, essential avoidance mediations in diabetic patients are particularly vital, especially measures to control the metabolic clutter in diabetes and those planned to control other cardiovascular hazard components that are habitually related. Essential anticipation measures must address wellbeing and eat less (starting with satisfactory control of count calories and abundance weight, visit direct physical work out, and the supreme cessation of smoking) 6-9 and pharmacological treatment. Once non-pharmacological measures have been presented, pharmacological treatment for the avoidance of the improvement of

cardiovascular illnesses in diabetic patients must be weighted.

Coronary course malady (CAD) is one of the most causes of morbidity and mortality within the world. Coronary supply route illness could be a condition characterized by a clinical continuum comprising of steady ischaemic heart malady (SIHD) extending from asymptomatic patients with subclinical or non-obstructive CAD to those who have obstructive CAD without self-evident angina (frequently alluded to as 'silent myocardial ischaemia') with or without past myocardial localized necrosis (MI), passing through the classical bunch enduring from inveterate steady angina and at last to patients with quick disintegration or dynamic angina that come full circle in intense coronary syndrome (ACS). In a nutshell, SIHD can be characterized as documentation of ischaemic heart malady within the nonappearance of later intense occasions; ordinarily the interim of time free from intense occasions is considered to be 12 months.

The pathophysiology of cardiac ischaemia includes the nearness of fibrotic and frequently calcific atherosclerosis (with a moo propensity to break) which limits blood stream inside a coronary supply route causing a disparity between the request and supply of oxygen to the myocardium. This happens in specific at the increment in heart rate and divider push of the cleared out ventricle; less visit elective instruments of ischaemia are plaque fit and microvascular brokenness.

Chronic angina therapy includes drugs that slow the progression of the disease and reduce cardiovascular events (ASA, statins) and drugs that improve symptoms and therefore the quality of life. With regard to the latter, there is clear scientific evidence of the effectiveness in reducing angina, while the data related to the reduction of 'hard' clinical endpoints (mortality, need for revascularization interventions, and MI) are much less solid. For this reason, the definition of optimal medical therapy in SIHD is not of univocal interpretation and presents substantial differences even among the clinical researches that have studied this pathology. In this work, we will analyse the state of the art in the pharmacological treatment of stable CAD.

## METHODOLOGY

Patient with NSTEMI-ACS can be divided into three categories ,mild ,moderate and high risk. Revascularization is the best option of treatment in patient with high risk ,while other groups of patients can be treated conservatively

## RESULTS

Fibrinolytic therapy is the best modality of treatment of patient with STEMI in Non-PCI capable hospital

With recently introduced high sensitivity Troponin ,MI can be detected more frequently and earlier in patients presenting with chest pain allowing a rapid rule-out protocol(3 hours).

Coronary CT angiography play a role in management of patients with CAD . Recently, Acute myocardial infarctions can be defined from a number of different perspectives related to clinical, electrocardiographic, biochemical and pathologic characteristics. The optimal treatment of STEMI should be based on the implementation of an emergency medical system (EMS) supervising a network between hospitals with various levels of technology, connected by an efficient ambulance service. Primary PCI should be performed within two hours after first medical contact (FMC), in the absence of contraindication and if primary PCI cannot be performed within the recommended time.
